(Received 16 January 2007; published 4 April 2007)

Here we will derive the general theory of the beam-breakup (BBU) instability in recirculating linear accelerators with coupled beam optics and with polarized higher-order dipole modes. The bunches do not have to be at the same radio-frequency phase during each recirculation turn. This is important for the description of energy recovery linacs (ERLs) where beam currents become very large and coupled optics are used on purpose to increase the threshold current. This theory can be used for the analysis of phase errors of recirculated bunches, and of errors in the optical coupling arrangement. It is shown how the threshold current for a given linac can be computed and a remarkable agreement with tracking data is demonstrated. General formulas are then analyzed for several analytically solvable problems: (a) Why can different higher order modes (HOM) in one cavity couple and why can they then not be considered individually, even when their frequencies are separated by much more than the resonance widths of the HOMs? For the Cornell ERL as an example, it is noted that optimum advantage is taken of coupled optics when the cavities are designed with an x-y HOM frequency splitting of above 50 MHz. The simulated threshold current is then far above the design current of this accelerator. To justify that the simulation can represent an actual accelerator, we simulate cavities with 1 to 8 modes and show that using a limited number of modes is reasonable. (b) How does the x-y coupling in the particle optics determine when modes can be considered separately? (c) How much of an increase in threshold current can be obtained by coupled optics and why does the threshold current for polarized modes diminish roughly with the square root of the HOMs’ quality factors. Because of this square root scaling, polarized modes with coupled optics increase the threshold current more effectively for cavities that have rather large HOM quality factors, e.g., those without very elaborate HOM absorbers. (d) How does multiple-turn recirculation interfere with the threshold improvements obtained with a coupled optics? Furthermore, the orbit deviations produced by cavity misalignments are also generalized to coupled optics. It is shown that the BBU instability always occurs before the orbit excursion becomes very large.

I. INTRODUCTION

In several applications of linear accelerators, the charged particle beam passes through the accelerating structures more than once after being led back to the entrance of the linac by a return loop. By this method the linac can either add energy to electrons several times, or it can recapture the energy of high energy electrons after they have already been used for experiments. The former technique is referred to as recirculating linac, the latter as energy recovery linac (ERL) [1].

ERLs have received attention in recent years since they have the potential to accelerate currents much larger than those of nonrecovering linacs, and since they have the potential for providing emittances smaller than those in x-ray storage rings at similar energies and for similar beam currents. This is due to the fact that the emittances in an ERL can be as small as that of the electron source, if emittance increase during acceleration can be avoided.

There are operating ERLs of relative small scale at TJNAF, JAERI, and Novosibirsk, and several laboratories have proposed high power ERLs for different purposes. Designs for light production with different parameter sets and various applications are being worked on by Cornell University [2,3], Daresbury [4], TJNAF [5], JAERI [6], Novosibirsk [7], and KEK [8]. TJNAF has incorporated an ERL in its design of an electron light-ion collider (ELIC) [9] for medium energy physics, while BNL is working on an ERL-based electron cooler [10] for the ions in the relativistic ion collider (RHIC) and a future electron-ion collider (eRHIC) [11] based on ERL. The first international ERL workshop with over 150 participants in early 2005 has also shown the large interest in ERLs that is prevalent in the accelerator community.

One important limitation to the current that can be accelerated in ERLs or recirculating linear accelerators in general is the regenerative beam-breakup (BBU) instability. The size and cost of all these new accelerators certainly requires a very detailed understanding of this limitation. In [12] we have described this theory for particle motion in 1 degree of freedom. Here we generalize this theory to 2 degrees of freedom, i.e., to accelerators with polarized HOMs and x-y coupling of the particle optics.

For 1 degree of freedom, a theory of BBU instability in recirculating linacs, where the energy is not recovered but added in each pass through the linac, was presented in [13]. This original theory was additionally restricted to scenarios where the bunches of the different turns are in the linac at

*Electronic address: Georg.Hoffstaetter@cornell.edu
about the same accelerating radio-frequency phase, such as in the so-called continuous wave (CW) operation where every bucket is filled. The theory was generalized in [14] to include the case of a subharmonic bunching scheme in the operation of such linacs. Tracking simulations [15] compared well with this theory. This theory determines above what threshold current \( I_{th} \) the transverse bunch position \( x \) displays undamped oscillations in the presence of a higher-order mode (HOM) with frequency \( \omega_A \). If there is only one higher-order mode and one recirculation turn with a recirculation time \( t_r \) in the linac, the following formula is obtained for \( T_{12} \sin \omega_A t_r < 0 \):

\[
I_{th} = -\frac{2e^2}{a(Q/Q)_A \omega_A} \frac{1}{T_{12} \sin \omega_A t_r},
\]

where \( c \) is the speed of light, \( e \) is the elementary charge, \( (R/Q)_A \) is the impedance (in units of \( \Omega \)) of the higher-order mode driving the instability, and \( Q_A \) is its quality factor. In the case of 1 degree of freedom, \( T_{12} = T_{12}^+ \) is the element of the transport matrix that relates initial transverse-momentum \( p_x \) before and \( x \) after the recirculation loop. A corresponding formula had already been presented in [16]. Occasionally, additional factors are found when this equation is stated [17–20], notably an exponential factor of \( e^{-\pi} \), \( e = \frac{\omega_c}{2Q} \). In [12] it has been shown that such additional factors are not required.

Especially [20] might support the false impression that an exponential factor should be contained in Eq. (1) because that paper provides exact formulas for two special cases, where (a) the bunch distance equals the length of the accelerator loop or (b) it equals half that length, which are both written with the noted exponential factor times an additional factor that tends to \( e \) for small \( \epsilon \). However, Eq. (1) is a linearization with respect to \( \epsilon \) and thus only applies where \( \epsilon e^{-\pi} = \epsilon \). A second order analysis shows that in case (a) the exponential leads to a second order in \( \epsilon \) that deviates from the correct factor by as much as that of Eq. (1), only the sign of the deviation is reversed. In (b), using the exponential factor actually increases the error of the second order term.

The beam transport element \( T_{12} \) appears since a HOM produces a transverse-momentum \( p_x \) during the first pass of a particle. This produces a transverse position of \( x = T_{12} p_x \) when the particle traverses the HOM for a second time, and this in turn excites the HOM itself by means of the wake function \( W_x = WT_{12} p_x \).

When the mode is polarized with an angle \( \theta \), the kick produced during the first turn corresponds to the momentum \( (p_x, p_y) = p(\cos \theta, \sin \theta) \). With a coupled optics, the resulting orbit displacement when the particle reaches the HOM after the return loop is \( \delta_x = p(T_{12} \cos \theta + T_{14} \sin \theta, T_{32} \cos \theta + T_{34} \sin \theta) \). This excites the higher-order mode by the projection of this displacement onto the wake function, \( \tilde{W} \cdot \delta x = WP[T_{12} \cos^2 \theta + (T_{14} + T_{32}) \times \sin \theta \cos \theta + T_{34} \sin^2 \theta] \).

The HOM therefore produces a transverse kick that feeds back to itself, exactly as in the case with 1 degree of freedom, only that \( T_{12} \) needs to be replaced [21] by

\[
T_{12}^+ = T_{12} \cos^2 \theta + (T_{14} + T_{32}) \sin \theta \cos \theta + T_{34} \sin^2 \theta. \quad (2)
\]

While Eq. (1) is derived with one HOM, for 1 degree of freedom it is often a good approximation even when the cavity has several higher-order modes. It was shown in [12] that different HOMs can be treated individually when their frequencies differ by more than about \( \frac{\omega_c}{2Q} \). This statement does not hold for 2 degrees of freedom as will be shown in this paper. Modes cannot in general be treated independently, even when their frequencies are separated by much more than the width of the HOM’s resonance.

An optics configuration that makes \( T_{12}^+ \) close to zero in order to make the threshold current very large has been proposed [22,23] and tested for coupled beam transport and polarized HOMs. This is a good technique when there is one dominant HOM. When there are several modes this approach does not apply directly, even if these modes are separated by more than the width of their resonance. This statement goes contrary to general wisdom, for example, as presented in [24], but it will be proven in the remainder of this paper.

The paper is arranged as follows: first, a dispersion relation for the current \( I_0(\omega) \) is derived including coupling in a single-turn recirculating linac with one cavity having multiple polarized HOMs. The smallest real value of \( I_0 \) that can be obtained with real \( \omega \) determines the threshold current. Analytical solutions are given for the case of two polarized HOMs in one cavity. It is explained how the dispersion relation for the simple case can be solved efficiently on a computer, and comparisons to analytical approximations are presented. Approximations are then given for \( N \) polarized modes in one cavity. Subsequently, a dispersion relation for multiple cavities and multiple recirculation loops is derived that can only be solved numerically with similarly efficient techniques. Finally, misalignments of cavities are considered to investigate when these misalignments lead to a very large static displacement of the beam orbit.

II. N POLARIZED MODES IN ONE CAVITY

For simplicity we are here investigating one cavity with \( N \) higher-order dipole modes (HOMs), each having a polarization angle \( \theta_A \) to the horizontal. Note that slightly polarized cavities often have at least two HOMs with similar characteristics, and looking at a single polarized HOM can therefore be misleading.

The unit vector in the direction of the polarization is \( \hat{e}_\theta = \cos \theta_A \hat{e}_x + \sin \theta_A \hat{e}_y \). The effective transverse voltage in each HOM is \( V_A \), so that a particle traversing this HOM obtains a transverse-momentum change of \( \hat{e}_x V_A \). When \( \hat{V} \) is the vector of all these \( N \) voltages, then the momentum
change is
\[
\Delta \tilde{p} = e \mathbf{E} \tilde{V}, \quad \mathbf{E} = (\tilde{e}_1 \ldots \tilde{e}_N).
\] (3)

When the particle returns to the cavity after the return time \( t_r \), the particle’s position has changed by
\[
\Delta \tilde{x}(t') = \mathbf{T} \Delta \tilde{p}(t' - t_r), \quad \mathbf{T} = \begin{pmatrix} T_{12} & T_{14} \\ T_{32} & T_{34} \end{pmatrix}.
\] (4)

This position will increase the voltage in \( V_\lambda(t) \) by the projection of the mode’s wake function \( W_\lambda(t - t') \tilde{e}_\lambda \) onto \( \Delta \tilde{x}(t') \) times the charge \( q(t') \) that excites the field, i.e.,
\[
I(t')W_\lambda(t - t')\Delta \tilde{x}(t')dt'.
\]
Integrating over all contributions to the HOM potentials leads to
\[
\tilde{V}(t) = \frac{e}{c} \int_{-\infty}^{t} I(t')W(t - t')D\tilde{V}(t' - t_r)dt'
\] (5)

with
\[
W = \text{diag}(W_\lambda), \quad D = \mathbf{E}' \mathbf{T} \mathbf{E}
\] (6)

and therefore
\[
D_{\mu\mu} = T_{12} \cos^2 \theta_\mu + T_{34} \sin^2 \theta_\mu + \frac{T_{12} + T_{14}}{2} \sin 2\theta_\mu,
\]
\[
D_{\mu\nu} = T_{12} \cos \theta_\mu \cos \theta_\nu + T_{34} \sin \theta_\mu \sin \theta_\nu + T_{32} \sin \theta_\mu \cos \theta_\nu + T_{14} \cos \theta_\mu \sin \theta_\nu.
\] (7)

Here \( I(t') \) is the current of the bunches that have already traveled for one turn; in the approximation of short bunches it is given by
\[
I(t) = I_0 t_b \sum_{m=-\infty}^{\infty} \delta(t - t_r - mt_b),
\] (8)

where \( t_b \) is the period of bunches. This transforms the integral equation into
\[
\tilde{V}(t) = I_0 \frac{e}{c} t_b \sum_{m=-\infty}^{\infty} W(t - t_r - mt_b)D\tilde{V}(mt_b),
\] (9)

where \( W_\lambda(t) = 0 \) for \( t \leq 0 \).

The Laplace transform of \( \tilde{V}(t) \) can be written as
\[
\tilde{V}(t + \delta t_b) = \frac{1}{2\pi} \int_{-\infty - ic_0}^{\infty - ic_0} \tilde{V}_\delta(\omega')e^{-i\omega t}d\omega',
\] (10)

where \( 0 < \delta < 1 \) and \( c_0 > 0 \). With the following definition
\[
\tilde{V}_\delta(\omega) = \sum_{n=-\infty}^{\infty} \tilde{V}_\delta(\omega + \frac{2\pi}{t_b} n),
\] (11)

one obtains
\[
\tilde{V}_\delta(\omega) = t_b \sum_{n=-\infty}^{\infty} \tilde{V}([n + \delta]t_b)e^{i\omega t_b}.
\] (12)

Since \( \tilde{V}_\delta(\omega) \) is periodic with \( 2\pi/t_b \), it has a Fourier series, and its Fourier coefficients are \( \tilde{V}([n + \delta]t_b) \), which shows that \( \tilde{V}_\delta(\omega) \) does not vanish. The transverse motion is stable when \( \tilde{V}(\omega) \) is zero for all \( \omega \) with positive imaginary part. If the current is increased the motion can become unstable at which point \( \tilde{V}(\omega) \) is nonzero for at least one \( \omega \) with positive imaginary part. At threshold it is therefore nonzero for a real value of \( \omega \).

As in [12] we will use \( t_r = (n_r - \delta)t_b \) to allow for all recirculating phases, e.g. \( \delta = \frac{1}{2} \) for an ERL. The integral equation now leads to a relation for these coefficients,
\[
I_r^{-1} \tilde{V}_\delta(\omega) = \frac{e}{c} t_b \sum_{m=-\infty}^{\infty} W([n - n_r - m + \delta]t_b)
\times D\tilde{V}(mt_b)e^{i\omega t_b}
= \frac{e}{c} e^{i\omega t_b} \tilde{W}_\delta(\omega)D\tilde{V}(0)\tilde{V}(\omega).
\] (13)

This formulation shows that \( \tilde{V}_\delta(\omega) \) is an eigenvector of the matrix on the right-hand side, and the corresponding eigenvalue is \( 1/I_0 \). Its solution is therefore very similar to the matrix theory for BBU computation without coupling in [13]. The threshold current can thus be determined by finding the largest real eigenvalue of this matrix for any real \( \omega \). Because of the symmetry properties \( \tilde{W}_\delta(\omega + \frac{2\pi}{t_b}) = \tilde{W}_\delta(\omega) \) and \( \tilde{W}_\delta(-\omega) = \tilde{W}_\delta(\omega) \), it is sufficient to investigate \( \omega \in [0, \pi/t_b] \) to find the BBU threshold current,
\[
I_{\text{th}}^{-1} = \frac{e}{c} \max \{ \lambda |e^{i\omega t_b} \tilde{W}_\delta(\omega)\mathbf{D}\tilde{V} = \lambda \tilde{V},
\lambda \in \mathbb{R}, \omega \in [0, \pi/t_b] \}.
\] (14)

A. Two polarized HOMs in one cavity

For a large number of HOMs this equation should be solved numerically, but for two HOMs an analytical solution is simple. The characteristic polynomial for the eigenvalue \( 1/I_0 \) becomes
\[
\begin{vmatrix} -\frac{I_0}{I_b} - D_{11} - \delta D_{13} & -D_{12} - \delta D_{13} \\ -D_{21} - \delta D_{13} & -\frac{I_0}{I_b} - D_{22} - \delta D_{13} \end{vmatrix} = 0,
\] (15)

with \( \bar{I} = \frac{e}{c} e^{i\omega t_b} I_0 \) and \( W_\lambda = \frac{1}{I_b} e^{i\omega t_b} (W_\lambda)_{\lambda \lambda} \). Solving this quadratic equation leads to
\[
\frac{c}{I_b} e^{-i\omega t_b} \frac{I_0^{-1}}{2} = \frac{D_{11} - \delta D_{13} - D_{22} + \Delta}{2} + \sqrt{\frac{(D_{11} - \delta D_{13} - D_{22} + \Delta)^2}{4} - w_1 w_2 D_{12} D_{21}}.
\] (16)

To increase the threshold current, the right-hand side of this formula should be small. The matrix \( \mathbf{D} \) is determined by the mode polarization and by the linear particle optics. It has been suggested [21,22] to use these parameters to
increase the threshold current. These suggestions amount to reducing the right-hand side of Eq. (16) by making $D_{11}$ and $D_{22}$ small. This is always a valid strategy if there is only one HOM, i.e. $w_2 = 0$. Then

$$D_{11} = T_{12} \cos^2 \theta_1 + T_{34} \sin^2 \theta_1 + \frac{T_{14} + T_{32}}{2} \sin 2\theta_1$$

(17)

and a horizontally ($\theta_1 = 0$) or a vertically ($\theta_1 = \pi$) polarized mode together with a beam transport that fully couples the vertical to the horizontal motion and vice versa, i.e. $T_{12} = T_{34} = 0$, would always lead to $D_{11} = 0$ so that there would not be any threshold current. A formula for this case has been derived in [21].

For the case of two or more HOMs this method is no longer as effective, even when the modes have very different frequencies. In fact it has been suggested that, in cases with several modes, each mode could be considered separately when each cavity mode has a resonance width which is significantly smaller than the frequency separation between modes [21]. This is however not correct and it will be seen shortly that the described method that would seem to increase the threshold current when all modes are considered separately is not as effective even when mode frequencies differ by much more than the resonance width. This is especially important when there are two HOMs of similar properties, for example, in nearly cylindrically symmetric cavities. To see this effect, we distinguish three cases.

### 1. Circular symmetry

For circular symmetric cavities there are two equivalent modes with perpendicular polarization, $w_1 = w_2$, $\tilde{e}_1 = \tilde{e}_2$, leading to $\mathbf{D} = \mathbf{T}$,

$$I_0 = \frac{c}{e \tau_b} \frac{e^{-i \omega t_1}}{T_{\pm} w_1},$$

$$T_{\pm} e^{i \delta_1} = \frac{T_{12} + T_{34}}{2} \pm \sqrt{\left(\frac{T_{12} - T_{34}}{2}\right)^2 + T_{14} T_{32}},$$

with $T_{\pm} \in \mathbb{R}^+$,

(18)

where the threshold current is the smaller of the two values obtained with the equation for $+ \delta$ and for $- \delta$. For $T_{12} = T_{34} = 0$ this case has been considered in [25]. If there is no coupling, $T_+ = |T_{12}|$ and $T_- = |T_{34}|$. This result is equivalent to what has been found in [12] for motion in 1 degree of freedom.

As in [12] we now use long-range wake functions of the form

$$W_{\lambda}(\tau) = \left(\frac{R}{Q}\right)_\lambda \omega_\lambda^2 2c e^{-(\omega_\lambda \tau)/(2Q_s)} \sin \omega_\lambda \tau,$$

(19)

where $Q_\lambda$ is the quality factor, $\omega_\lambda$ is the frequency, and $(R/Q)_\lambda$ is the impedance in units of $\Omega$ for the linear definition (2 times the circuit definition). As shown in [12], $|w_\lambda(\omega)|$ is especially large when $\omega$ is close to $\omega_\lambda$.

When motion in only one dimension is considered as in [12], one obtains

$$I_0 = \frac{c}{e \tau_b} \frac{e^{-i \omega t_1}}{T_{12} w_\lambda}.$$ 

(20)

For simplicity we again use $K_{\lambda} = t_b ([e \omega_\lambda^2]/[2c^2])_\lambda$ and $\epsilon_\lambda = \omega_\lambda^2 / 2c^2$. For $n, \epsilon_\lambda \ll 1$ this leads to the approximation

$$I_{\text{th}} = \begin{cases} \frac{- \epsilon_\lambda}{K_{\lambda} T_{12}} e^{-i \omega_\lambda t_1}, & \text{for } T_{12} \sin(\omega_\lambda t_1) < 0, \\ \frac{2}{K_{\lambda} T_{12}^2} \sqrt{\frac{\epsilon_\lambda^2}{n} + \left(\frac{\sin(\omega_\lambda t_1 + \delta_\lambda)}{n}\right)^2} & \text{else}. \end{cases}$$

(21)

For $\epsilon_\lambda \ll 1$ but $n, \epsilon_\lambda \gg 1$, the approximation derived in [12] is

$$I_{\text{th}} = \frac{2 \epsilon_\lambda}{K_{\lambda} T_{12}}.$$ 

(22)

In the case of coupled optics exactly the same approximation and derivation therefore leads from Eq. (18) to

$$I_{\text{th} \pm} = \begin{cases} \frac{- \epsilon_\lambda}{K_{\lambda} T_{12}^2} \sin(\omega_\lambda t_1 + \delta_\lambda), & \text{if it is } > 0, \\ \frac{2}{K_{\lambda} T_{12}^2} \sqrt{\frac{\epsilon_\lambda^2}{n} + \left(\frac{\sin(\omega_\lambda t_1 + \delta_\lambda)}{n}\right)^2} & \text{else}. \end{cases}$$

(23)

For $\epsilon_\lambda \ll 1$ but $n, \epsilon_\lambda \gg 1$,

$$I_{\text{th} \pm} = \frac{2 \epsilon_\lambda}{K_{\lambda} T_{12}}.$$ 

(24)

The threshold current is given by $I_{\text{th}} = \min(I_{\text{th} \pm})$.

To clarify the case considered here, we use typical parameters for the two HOMs: $Q_1 = Q_2 = 10^4$, $K_1 = K_2 = 100 \Omega$, $\omega_1 = \omega_2 = 2 \pi \times 2.2 \text{ GHz}$, $t_b = 1/1.3 \text{ GHz}$, $n_r = 5.5$. For a decoupled optics with $T_{12} = -10^{-6} \frac{m}{\text{m/s}}$, $T_{14} = T_{32} = 0$, we obtain a threshold current of $I_{\text{th}} = 46.40 \text{ mA}$ that agrees to all specified digits when computed by particle tracking and by the approximation in Eq. (24). For a very much coupled beam transport (abbreviation $x = -10^{-6} \frac{m}{\text{m/s}}$ is used below), the following threshold current is obtained:

$$\mathbf{T} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & x & 1 & 3x \\ 0 & 1 & 0 & 1 \\ -1 & -2x & 1 & 4x \\ 0 & -1 & 0 & 1 \end{pmatrix} \Rightarrow I_{\text{th}} = 20.28 \text{ mA}.$$ 

(25)

Again the threshold current computed by particle tracking and by Eq. (23) agrees to all specified digits.
2. Small coupling

We refer to the case with \(|D_{11}w_1 - D_{22}w_2|^2 \gg |w_1w_2D_{12}D_{21}|\) as small coupling. This denomination is motivated by the fact that, when one mode is polarized in \(x\) and one in \(y\) direction, this case occurs when the optical coupling is small, as can be seen in Eq. (7). Equation (16) simplifies to

\[
I_0 = \frac{c}{\epsilon l_b} \frac{e^{-i\omega t_r}}{D_{AA} w_A},
\]

with \(\lambda\) being either 1 or 2.

The approximation that leads from Eq. (20) to Eq. (21) can again be used and it leads to

\[
I_{th} \approx -\frac{2\epsilon \lambda}{K \lambda D_{AA} \sin(\omega_A t_r)} \quad \text{for } D_{AA} \sin(\omega_A t_r) < 0,
\]

and similarly an approximation that corresponds to Eq. (22) is valid. This formula has been used to argue that an optics with very small \(|D_{AA}|\) could be built with extremely large threshold current. But this equation does not apply when the \(|D_{AA}|\) are too small, since then the following case has to be considered.

3. Strong coupling

We refer to the case with \(|D_{11}w_1 - D_{22}w_2|^2 \ll |w_1w_2D_{12}D_{21}|\) as strong coupling. This case is especially relevant when the mentioned coupling techniques have been used to make \(D_{11}\) and \(D_{22}\) very small. One obtains

\[
I_0^2 \approx \left(\frac{c}{\epsilon l_b}\right)^2 \frac{e^{-i\omega t_r}}{w_1 w_2 D_{12} D_{21}}.
\]

At the threshold current only one of the functions in the denominator will be very large and we call this \(w_{\mu}\). The other mode will be indexed by \(\nu\).

In [12] a first order approximation in \(\Delta \omega t_b = (\omega - \omega_{\mu}) t_b\) and \(\epsilon_{\mu}\) is used to obtain Eqs. (21) and (22). We here again expand to first order in these quantities, which is simple since \(w_{\mu}^{-1}\) is linear in them so that \(w_{\mu}^{-1}\) can be evaluated at \(\Delta \omega = 0\) and \(\epsilon_{\nu} = 0\), leading to

\[
I_0^2 = \frac{c}{\epsilon l_b} \frac{e^{-i\omega t_r + \delta}}{Tw_1},
\]

with \(Te^{i\delta} = e_{\nu} w_\nu (\omega_{\mu}) D_{12} D_{21}, \ T \in \mathbb{R}^+\). Note that the exponent contains \(2t_r\) instead of \(t_r\). The approximations that correspond directly to Eqs. (23) and (24) can again be applied.

In [12] \(w_{\lambda}\) is evaluated for the long-range wake function, leading to

\[
\begin{align*}
I_0 &= \frac{c}{\epsilon l_b} \frac{e^{-i\omega t_r}}{D_{AA} w_{\lambda}}, \\
&= \frac{R}{4c} \omega_{\lambda}^2 \frac{\sin(\omega_{\lambda} t_r)}{\omega_{\lambda} t_r} \frac{\cos(\omega_{\lambda} t_r)}{\cos(\omega_{\lambda} t_r)}
\end{align*}
\]

\[
\begin{align*}
&\times e^{i\omega(\delta - 1)t_r} \sin(\omega_{\lambda} \delta t_r) - e^{i\omega(\delta - 1)t_r} \sin(\omega_{\lambda} \delta t_r) \frac{\cos(\omega_{\lambda} t_r)}{\cos(\omega_{\lambda} t_r)} \\
&= \frac{R}{4c} \omega_{\lambda}^2 \cos(\omega_{\lambda} t_r) \sin(\omega_{\lambda} t_r) - \cos(\omega_{\lambda} t_r) \sin(\omega_{\lambda} t_r) \\
&= \frac{R}{4c} \omega_{\lambda}^2 \sin(\omega_{\lambda} t_r) \frac{\cos(\omega_{\lambda} t_r)}{\cos(\omega_{\lambda} t_r)}
\end{align*}
\]

\[
(30)
\]

Note that here \(w_{\lambda}\) is defined without a phase factor \(e^{-i\omega_{\lambda} t_r}\) compared to [12] to simplify the notation. For an ERL, where \(\delta = 1/2\), one has

\[
I_0 = \frac{R}{4c} \omega_{\lambda}^2 \cos(\omega_{\lambda} t_r) \sin(\omega_{\lambda} t_r)
\]

\[
(31)
\]

with \(\omega_{\lambda} t_r = \omega t_r + i \epsilon_{\lambda}\). Then \(\omega = \omega_{\mu} + \Delta \omega\) with the small quantity \(\Delta \omega t_b\). We assume that also \(\epsilon_{\lambda} = \omega t_r / 2\). An interesting observation is that for two modes with \(\mu = 1, 2\) and \(\mu = 1, 2\), the ratio of the threshold current \(I_{th}\), the right-hand side has to be a real number, requiring \(\Delta \omega t_r = \sin(2t_r)\). This leads to

\[
I_{th}^2 = \frac{2\epsilon_{\mu}}{K \lambda \epsilon_{\nu} D_{12} D_{21} \cos(\omega_{\mu} t_r / 2) \sin(\omega_{\nu} t_r / 2)}
\]

\[
(32)
\]

\[
I_{th}^2 = \frac{2\epsilon_{\mu}}{K \lambda \epsilon_{\nu} D_{12} D_{21} \cos(\omega_{\mu} t_r / 2) \sin(\omega_{\nu} t_r / 2)}
\]

\[
(33)
\]

whenever this term is positive. Whenever it is negative, the following approximation follows from [12]:

\[
I_{th}^2 = \frac{2\epsilon_{\mu}}{K \lambda \epsilon_{\nu} D_{12} D_{21} \cos(\omega_{\mu} t_r / 2) \sin(\omega_{\nu} t_r / 2)}
\]

\[
(34)
\]

For \(\epsilon_{\mu} \ll 1\) but \(n, \epsilon_{\mu} \gg 1\), one obtains

\[
I_{th}^2 = \frac{2\epsilon_{\mu}}{K \lambda \epsilon_{\nu} D_{12} D_{21} \cos(\omega_{\mu} t_r / 2) \sin(\omega_{\nu} t_r / 2)}
\]

\[
(35)
\]

These formulas are to be evaluated for \(\mu = 1, \nu = 2\) and for \(\mu = 2, \nu = 1\), and the smaller of the two resulting currents is the threshold current,

\[
I_{th} = \min\{I_{th\mu}, \mu \in \{1, 2\}\}
\]

\[
(36)
\]

An interesting observation is that for two modes with similar \(Q_{\lambda}\), \(Q_{2\lambda}\), and \(\omega_{\lambda}\), the ratio of the threshold current with and without coupled optics can be found by comparing Eqs. (33) and (27) and it is proportional to \(\sqrt{I}$/\epsilon_{\lambda} \propto \sqrt{Q_{\lambda}}\). For cavities that are optimized for large currents by means of sophisticated HOM damping, the advantage of a coupled optics therefore decreases. This effect is indepen-
FIG. 1. (Color) The threshold with two modes in one cavity scales with $Q^{-1}$ for a decoupled (red, bottom curve) and with $Q^{-1/2}$ for a fully coupled optics (blue, top curve). The advantage of coupling thus diminishes for low $Q$.

A closer look shows that the slope is only accurately $-1$ for relatively small and relatively large $Q$ where either approximation (21) or (22) holds. A totally coupled optics with $T_{12} = 0$ and $T_{34} = 0$ leads to a larger threshold current than without coupling, but when $Q$ of the modes is reduced, the threshold current increases only with $Q^{-1/2}$ as indicated by a line with slope $-1/2$. The advantage of coupling decreases proportionally to $\sqrt{Q}$.

For Table I the 320 cavities of the ERL upgrade of CESR had nominal HOM frequencies of $f_{x1} = 1.87394$ GHz and $f_{x2} = 1.88173$ GHz with horizontal polarization. The mode with vertical polarization is $f_y = f_x - \Delta f_{xy}$. The cavities have HOM frequencies that have a Gaussian distribution around these values with rms width $\sigma_{f_y}$. We used 500 different random distributions of the frequencies and display the average threshold current $I_{th}$ as well as the rms $\sigma_I$ of the 500 resulting thresholds.

FIG. 2. (Color) Scaling with $Q$ of the threshold increase due to coupling for the x-ray ERL upgrade of CESR. Red, bottom curve: scaling with $Q^{-1}$ for a decoupled optics. Blue, top curve: a line indicates scaling with $Q^{-1/2}$, the points are obtained for a fully coupled optics.

The eigenvalues are largest in the vicinity of the origin of the complex plane about once per variation of $w/\lambda_b$. Large factors in speed can be gained when the loops that are traced out by each eigenvector can be interpolated and their intersection with the real axis, and fitting an upright ellipse to these values is a very good parametrization. The accuracy achieved for distributing $k$ particles in the described region around each HOM frequency leads to the accuracy documented in Fig. 4.

B. Comments about numerical solutions

When the threshold current for two polarized modes at $\omega_\rho$ and $\omega_\mu$ should be found by solving Eqs. (26) and (28) numerically, the eigenvalues are plotted in the complex plane, and the intersections with the real axis are sought that lead to the smallest current. An example of the two eigenvalues plotted in the complex plane is shown in Fig. 3. The eigenvalues are largest in the vicinity of $\omega = \text{mod}_\omega(\omega_\rho, \frac{2\pi}{\lambda_b})$, $\lambda \in \{1, 2\}$, since there either $w_\mu$ or $w_\rho$ become very large. The subscript on the mod function indicates that $\text{mod}_\omega(x, 1) \in [0, 1]$ and $\text{mod}_\omega(x, 1) \in [-\frac{1}{2}, \frac{1}{2}]$.

Furthermore, the eigenvalues trace out loops around the origin of the complex plane about once per $\frac{2\pi}{\lambda_b}$ variation of $\omega$, due to the exponential factor in Eq. (26). We therefore vary $\omega$ only in a $\pm \frac{2\pi}{\lambda_b}$ interval around each HOM frequency. This speeds up the search for eigenvalues by a factor proportional to $n_\omega$, which can be very large.

A simple approach would be to plot all eigenvalues in the complex plane and to select the smallest eigenvalue that is reasonably close to the complex plane. Large factors in speed can be gained when the loops that are traced out by each eigenvector can be interpolated and their intersection with the real axis can be found, since the loops have to be scanned much less densely. We have found that using values of $I_{\text{th}}(\omega)$, where two are above and two below the real axis, and fitting an upright ellipse to these values is a very good parametrization. The accuracy achieved for distributing $k$ particles in the described region around each HOM frequency leads to the accuracy documented in Fig. 4.

C. Comparison of results for polarized modes and coupling

To demonstrate the excellent agreement between these numerical solutions and tracking, we depict Fig. 5 where one HOM with horizontal polarization has been fixed at $f_\rho = 2.2$ GHz, and another has been varied for $f_\mu \in [1.2, 3.2]$ GHz. The optics was completely coupled with $T_{12} = T_{34} = 0$ and $T_{31} = -T_{14} = 10^{-6} \frac{\text{m}}{\text{eV/c}}$. Several things can be observed: (1) since tracking is relatively time consuming, only relatively few frequencies for the second HOM have been evaluated, but all of them lie exactly on the curve that follows from the dispersion relation. (2) The threshold current varies strongly when

While these threshold currents were simulated with only the 4 most destructive HOMs in each cavity, we have seen that including more modes does not strongly diminish the threshold current, as shown in Table II. A more detailed account of threshold simulations for the x-ray ERL can be found in [27]. Characteristics of the 8 modes that were used are shown in Table III.

B. Comments about numerical solutions

The accuracy achieved for distributing $k$ particles in the described region around each HOM frequency leads to the accuracy documented in Fig. 4.
the second HOM is varied, but the agreement with tracking
shows that this is not numerical noise but a consequence of
the coupling between the two polarized modes whose
frequencies are very far apart. (3) There are frequencies
where the threshold current is relatively small, these are
frequencies where
\[ \cos(\omega_1 t_b) = \cos(\omega_2 t_b) \]
in agreement with Eq. (32). The displayed minima appear at
\[ 2.5 \text{ GHz}, 2.2 \text{ GHz}, \text{ and } 2.5 \text{ GHz} \]. But the
regions with reduced threshold are relatively wide; in
particular, they are much wider than the width of HOM
resonances.

Depicted in color are the values obtained by approxima-
tions derived above. It is apparent that the approximations
are not always very good, especially that they lead to
values that are too large. A magnification in Fig. 6 shows
that the reason for that is that the approximate formulas
lead to parabolic shapes that have the correct minimum
value, but not the correct width. This is important since it
shows that the formulas can be used to find the correct
minimum value as a conservative estimate. Furthermore,
the magnifications again show the good agreement with
tracking results.

Here an important note is in place. One place where a
strong dip occurs is when \( \omega_1 = \omega_2 \). This dip is much wider
than the width of the HOM resonance of \( \omega_\lambda/Q_\lambda \), showing
that the two modes clearly do not decouple when they are
separated by more than their width. For nominally circular
symmetric cavities, HOMs are not degenerate due to con-
struction errors and each mode splits into two modes with
typically a few MHz distance. But the dip is much wider
than that, showing that an appropriate advantage of BBU
suppression by damping can in general only be realized
when polarized cavities are designed, i.e., cavities where
the horizontal and vertical dimensions are designed to be

slightly different, leading to HOM frequencies that differ
by several 10 MHz in the two planes.

The question arises how far the HOM frequencies have
to be apart. In Fig. 7 we show for the Cornell ERL how \( I_{th} \)
changes with \( \Delta f_{xy} \). In order to avoid averaging over many

![FIG. 5. (Color) Threshold current for one horizontal HOM with
\( f_x = \omega_x/2\pi = 2.2 \text{ GHz} \) as a function of the frequency \( f_y \)
of a vertical HOM. Black curve: dispersion relation; red dots: track-
ing; green dots: the approximation derived above. For clarity, a
subinterval of this graph is shown in Fig. 6.]

![FIG. 6. (Color) Magnification of regions in Fig. 5.]

![FIG. 7. Dependence of \( I_{th} \) on \( \Delta f_{xy} \) for the Cornell ERL.]
different frequency distributions, we have here chosen the same two HOM frequencies for each of the 320 cavities. The data indicates that a mode separation of 60 MHz is sufficient. This has been used to compute the very large recirculating BBU threshold current of more than 2 A for this accelerator shown in Table I. It should be noted that only the two dominant HOMs were considered in this simulation, more modes are considered in [27]. The Cornell ERL is designed for 100 mA and this calculation indicates that polarized cavities with a coupled optics provide a very comfortable safety margin with respect to this instability. However, Table I shows that, even without a coupled optics but with a distribution of HOM frequencies, a sufficient $I\theta$ can be obtained, making polarized cavities not absolutely necessary.

While the advantage of introducing the 60 MHz mode separation is significant, there are problems associated with changing the cavity geometry to produce such a separation. For instance, higher-order multipole fields and associated focusing effect as well as interferences between modes of neighboring passbands could have unpleasant consequences. We are currently designing a suitable polarized 7-cell cavity to analyze these questions.

D. Approximation for $N$ polarized HOMS in one cavity

As a first approximation, one can assume that one component of the eigenvectors in Eq. (13) will be very large. This would lead to a decoupling of HOMs so that each HOM could be treated separately, as for a single degree of freedom. One could therefore derive the threshold with the smallest current for each individual HOM, and this would approximate the threshold for the complete accelerator. When all these thresholds are very large, one has to investigate the next approximation, where the eigenvector has two dominant components. In this case the eigenvalues are determined from a $2 \times 2$ matrix corresponding to Eq. (15). The threshold current has to be computed for each pair of HOMs. The smallest current obtained for one pair of polarized modes then approximates the threshold current of the full accelerator.

III. POLARIZED HOMS IN MANY CAVITIES AND FOR MULTIPLE TURNS

Recirculating linacs with many cavities and several recirculation loops have been considered early on [13,28]. In [12] a description for arbitrary recirculation times has been presented. Here we want to extend this description to include orbit coupling and polarized modes. As far as possible, we retain the notation of these earlier papers. The $N$ higher-order modes, which can be associated with different cavities, are numbered by an index $i$. The $N_p$ passes through the linac are numbered by an index $j$. The horizontal and vertical phase space coordinates that the beam has at time $t$ in the HOM $i$ during turn $I$ is denoted $\mathbf{z}_i^I(t) = [x_i^I(t), p_{x_i}^I(t), y_i^I(t), p_{y_i}^I(t)]^T$. The $4 \times 4$ transport matrix that transports the phase space vector $\mathbf{z}_i^I(t)$ at HOM $j$ during turn $J$ to $\mathbf{z}_j^{I+1}(t)$ is denoted $\mathbf{T}_{ij}^{I+1I}$ and the time it takes to transport a particle from the beginning of the first turn to HOM $i$ during turn $I$ is denoted $t_i$. The beam is propagated from after HOM $i - 1$ to after HOM $i$ by

$$\mathbf{z}_i^I(t) = \mathbf{T}_{ii-1}^{IJ} \cdot \mathbf{z}_{i-1}^{I-1}(t - [t_i^I - t_{i-1}^I]) + \frac{e}{c} \mathbf{V}_i(t),$$

(37)

with $\mathbf{V}_i = V_i(0, \cos \theta_i, 0, \sin \theta_i)^T$. This equation can be iterated to obtain the phase space coordinates as a function of the HOM strength that creates the orbit oscillations. With the matrix

$$\mathbf{T}_{ij}^{IJ} = \begin{pmatrix} \mathbf{T}_{ij}^{IJ}_{12} & \mathbf{T}_{ij}^{IJ}_{132} \\ \mathbf{T}_{ij}^{IJ}_{32} & \mathbf{T}_{ij}^{IJ}_{34} \end{pmatrix},$$

(38)

one obtains

$$\mathbf{z}_i^I(t) = \sum_{j=1}^{N_p} \sum_{j=1}^{N_p} \mathbf{T}_{ij}^{IJ} \mathbf{e}_j \frac{e}{c} \mathbf{V}_j(t - [t_i^I - t_j^I]),$$

(39)

$$N_{ij}(i - 1) = \begin{cases} N_i, & \text{if } i \neq J; \\ i - 1, & \text{if } i = J. \end{cases}$$

(40)

The strength $V_j(t)$ of the HOM $i$ with polarization direction $\mathbf{e}_j$ is created by all particles that have traveled through that HOM via the integral

$$V_i(t) = \int_{-\infty}^{\infty} \sum_{j=1}^{N_p} W_j(t - t') I_i^j(t') \mathbf{e}_j^T \mathbf{z}_i^j(t') dt',$$

(41)

where $I_i^j(t)$ is the current which the beam has on its $I$th turn at the HOM $i$. Note that $W(t - t') = 0$ for $t' > t$. Combining this with Eq. (39) leads to the following integral-difference equation:

$$V_i(t) = \int_{-\infty}^{\infty} \sum_{j=1}^{N_p} W_j(t - t') I_i^j(t') \frac{e}{c}$$

$$\times \sum_{j=1}^{N_p} \sum_{j=1}^{N_p} D_{ij}^{I} \mathbf{V}_j(t' - [t_i^I - t_j^I]) dt',$$

(42)

$$D_{ij}^{I} = \mathbf{e}_j^T \mathbf{T}_{ij}^{IJ} \mathbf{e}_j.$$  

(43)

This equation is identical to that obtained for 1 degree of freedom, only that $(\mathbf{T}_{ij}^{IJ})_{12}$ is replaced by $D_{ij}^{I}$. The following treatment for obtaining the threshold current is therefore identical to that in [12]. For completion it is here presented in simplified form, and recommendations for numerical solutions are given.

Now the approximation of short bunches is used. The current is given at time $t$ by pulses that are equally spaced with the distance $t_b$,

$$I_i^j(t) = \sum_{m=\infty}^{\infty} I_0 I_b \delta(t - t_i^j - mt_b).$$

(44)
This reduces the integral to a sum,
\[
V_i(t) = \frac{e}{c} I_0 t_b \sum_{m=-\infty}^{\infty} \sum_{j=1}^{N_p} W_j(t - t_i' - mt_b)
\times \sum_{j=1}^{I_n(i-1)} \sum_{j=1}^{I_n(i-1)} D_{ij}^I V_j(mt_b + t'_j).
\]
This leads to
\[
\hat{V}_{i,t_i'/t_b}^\Sigma(\omega) = \frac{e}{c} I_0 t_b \sum_{m=-\infty}^{\infty} \sum_{j=1}^{N_p} W_j(mt_b + t'_j) \times \sum_{j=1}^{I_n(i-1)} \sum_{j=1}^{I_n(i-1)} D_{ij}^I \hat{V}_j(t'_{j} + t'_j).
\]
Furthermore, the dimension can be reduced when two fractional parts \(\delta_i^t\) and \(\delta_i'^t\) are equal since then \(V_i^t\) and \(V_i'^t\) are identical.

### A. Multiturn operation and cavity misalignments

Since the formalism presented here includes polarized modes and coupled optics is identical to the formalism in 1 degree of freedom, only that \((V_i^t)_{12}\) has been replaced by \(D_{ij}^t\), all conclusions about multturn recirculating and multiturn ERLs hold. For example, in [12] it was concluded that, for one HOM and for \(N_p\) passes through the linac, the threshold current should roughly scale as \(N_p(2N_p - 1)\). The origin of this conclusion results from the double sum \(\sum_{i=1}^{N_p} \sum_{j=1}^{I_n(i-1)}\). Since the same summation appears, this conclusion holds also for polarized modes with coupling.

While this quadratic scaling with \(N_p\) also applies without polarized modes and without coupling, there is an additional problem in the case of coupled optics that is designed to reduce the absolute values of all:
\[
D_{ij}^t = T_{12}^t \cos \theta_{ij} + T_{34}^t \sin \theta_{ij} + \frac{T_{14}^t + T_{32}^t}{2} \sin \theta_{ij}.
\]
Choosing polarized cavities so that \(\sin 2\theta_{ij} = 0\) for all modes and using fully coupled optics makes all \(D_{ij}^t\) zero for a one turn ERL leading to the approximate threshold current in Eq. (32). For a two turn ERL, \(D_{ij}^t\) for the first turn and \(D_{ij}^t\) for the second turn become zero. However, \(D_{ij}^t\) for both turns is in general not zero. Since \(T_{13} = T_{32} = T_{14} = 0\), full coupling with \(T_{12}^t = T_{34}^t = 0\) and \(T_{12}^t = T_{34}^t = 0\) leads to
\[
T_{12}^t = T_{12}^t \cot T_{12}^t + T_{34}^t \cdot T_{12}^t,
\]
\[
T_{14}^t = T_{34}^t \cot T_{14}^t + T_{34}^t \cdot T_{14}^t.
\]
While the optics can be fine-tuned so that \(T_{12}^t = T_{34}^t = 0\) holds for the location of one cavity, it will in general not hold for all cavities along a linac. The reason is that the transport of the first turn couples a horizontal oscillation that starts in the first pass through the linac into the vertical oscillation during the second pass, which in turn couples back into a horizontal oscillation during the third pass.

For misaligned cavities, HOMs are excited even when the current is smaller than the threshold current. This can lead to large beam excursions, and in [12] it was analyzed for what currents these excursions become extremely large. It was found that the BBU threshold current is always smaller than the current for which these orbit excursions would get very large. Since the formalism presented here with coupling and polarized modes has the same formal structure, this conclusion again holds.
B. Comments about numerical solutions

As pointed out above where numerical solutions for one return loop and two HOMs were found, it is very essential to systematically search for real values for the eigenvalues of $M$. Each eigenvalue traces out curves in the complex plane when $\omega$ is varied in the region $[0, \pi/t_b]$, however eigenvalue finders usually do not return eigenvalues in any particular order, so that these curves cannot be observed easily. If they could be observed, then ellipses could be fitted to these curves and the intersection of the curve with the real axis could very efficiently be found for each eigenvector.

We therefore recommend a sorting algorithm that sorts eigenvalues rather robustly: (1) Normalize each eigenvector. (2) Sort these vectors according to their largest component, i.e., the vector which has its largest component in position 1 is the first vector, if there are more than one of this kind, the one with the largest coefficient can be chosen as first vector, etc. (3) Associate the eigenvalues in the order of these eigenvectors. Small changes of $\omega$ do not change the relative size of the eigenvector elements much. The intersection of the curve $\lambda_i(\omega)$ with the real axis can now be found for each eigenvector. This procedure leads to an enormous speed advantage over simply scanning all eigenvalues for a mesh of $\omega \in [0, \pi/t_b]$, and choosing the largest eigenvalue that is reasonably close to the real axis.
